## Question 4 (18 points):

When generating initial code, a compiler generates naive code where the instructions for the execution of each memory access or for the computation of each expression is done independently of other such accesses or computation in the code. Consider the following function written in C to compute the Hadamard product of two vectors:

```
void Hadamard(int *A, int *B, int N){
      for(i=0; i<N; i++){
             A[i] = A[i] * B[i];
      }
}
        7 HadamardNaive:
                          t0, zero, zero # i <- 0
                  add
         loop:
                          t0, a2, done
                                         # if i >= N goto done
                 bge
                                          # t1 <- 4*i
                  slli
                          t1, t0, 2
       11
                                          # t2 <- Address(A[i])</pre>
                                                                    24 HadamardOpt:
                  add
                          t2, a0, t1
                          t3, 0(t2)
                                          # t3 <- A[i]
                                                                    25
                                                                                slli
                                                                                        t0, a2, 2
                                                                                                        # t0 <- 4*N
                                                                                                        # t1 <- Address(A[N])</pre>
                  slli
                          t4, t0, 2
                                          # t4 <- 4*i
                                                                    26
                                                                                add
                                                                                        t1, a0, t0
                                          # t5 <- Address(B[i])
       14
                  add
                          t5, a1, t4
                                                                                bge
                                                                                        zero, a2, done
                                                                                                       # if(0<=N) done
       15
                  lw
                          t6, 0(t5)
                                          # t6 <- B[i]
                                                                    28 loop:
                                                                                lw
                                                                                        t2, 0(a0)
                                                                                                        # t2 <- A[i]
                                          # t7 <- A[i]*B[i]
                                                                                                        # t3 <- B[i]
       16
                  mul
                          t7, t3*t6
                                                                    29
                                                                                1w
                                                                                        t3, 0(a1)

                                                                                        t4, 0(a0)
                                                                                                        # A[i] <- A[i]*B[i]
                                                                    31
                                                                                SW
                          t7, 0(t9)
                                          # A[i] <- A[i]*B[i]
                                                                                addi
                                                                                        a0, a0, 4
                                                                                                        # pA++
                  sw
                  addi
                                                                                addi
                                                                                        a1, a1, 4
                          t0, t0, 1
                                          # i <- i+1
                                                                                                        # pB++
                  jal
                          zero, loop
                                                                                        a0, t1, loop
                                                                                                        # if pA < Address(A[N])</pre>
                                                                                blt
                 jalr zero, ra, 0
(a) Naive Version
       22 done:
                                                                     35 done:
                                                                                    zero, ra, 0
                                                                                jalr
                                                                                     (b) Optimized Version
```

Figure 1: Two versions for a Dot Product function.

Figure ?? shows the RISC-V assembly code for a naive version and for an optimized version of the this function. In this question you will study the performance of these two versions. A performance study was conducted to determine the average number of clock cycles for different types of instructions. Based on this study, the instructions used in Figure ?? are classified into the following classes of instructions:

```
ALU Instructions (add, slli, addi): 1 cycle

Jumps and Branches (bge, blt, jal, jalr): 3 cycles

Memory instructions (lw, sw): 5 cycles

Multiplication Instructions (mul): 10 cycles
```

a. (3 points) Assuming that N is very large, what is the CPI of the naive version and what is the CPI of the optimized version?

b. (	4	points	) Again,	assuming	that N	is verv	large.	which	version	is	faster	and	by	how	much	1?

c. (5 points) A given invocation of the optimized version of Hadamard executes in 15 seconds in a baseline machine with a clock cycle of 2 GHz (1 GHz = 10<sup>9</sup> Hz). What was the value of N for this invocation of the Hadamard function?

- d. (6 points) A new version of the same processor has been designed that implements the following changes:
  - The clock frequency is 3 GHz
  - The average number of cycles required to execute memory instructions is reduced to 3 cycles
  - The number of cycles required to execute a multiplication instruction is also reduced

To discover what is the average number of cycles required to execute a multiplication operation in this new version of the machine you run an experiment where you execute the optimized version of Hadamard with  $N = 2 \times 10^6$ . You find out that the execution of such an invocation of Hadamard takes 12.7 ms (1  $ms = 10^{-3} seconds$ ). What is the average number of cycles required for multiplication operations in this new version of the machine?
